Keywords: Nitrous oxide, soil moisture, animal treading, nitrification inhibitor.

Introduction

Nitrous oxide (N₂O) is a potent greenhouse gas with a long-term global warming potential about 298 times that of carbon dioxide (CO₂). In grazed grassland, most of the N₂O is emitted from nitrogen (N) excreted by the grazing animal, particularly in the animal urine. When the soil is wet, such as in winter grazing conditions, animal grazing can cause soil structural damage, leading to soil compaction. The combination of a wet soil plus soil compaction is particularly conducive for N₂O production. A nitrification inhibitor technology using dicyandiamide (DCD) has been developed to reduce N₂O emissions from grassed grassland (Di and Cameron 2002; 2003). However, the efficacy of this technology under wet and compact soil conditions has not been well studied.

The objectives of this study were to determine: (1) The impact of soil moisture content on the abundance of ammonia oxidizers and N₂O emissions; (2) the impact of animal treading on N₂O emissions; and (3) The effectiveness of the nitrification inhibitor DCD in reducing N₂O emissions, as affected by soil moisture status and animal treading.

Materials and methods

A laboratory incubation study was conducted to determine the effect of soil moisture status on the abundance of ammonia oxidizers and N₂O emissions using a grassland soil (Horotiu soil: Typic Udovitrand). Two sets of incubations were set up, one set for soil sampling to determine the ammonia oxidizer abundance and the other set for determining N₂O emissions using a method similar to the static chamber methods by filling up glass bottles to two thirds the height and leave the top third as air space in the top 5 cm soil layer, and led to significant increases in N₂O emissions (Fig. 1). Trampling increased average cumulative N₂O emissions over a three month period from 15.9 kg N₂O-N/ha to 45.0 kg N₂O-N/ha in the soil that received animal urine. Total N₂O emissions from the soil at 130% field capacity were 400 times higher than those from the soil at 60% field capacity. Total N₂O emissions were significantly related to the abundance of AOB amoA gene copy numbers but not to that of the AOA.

Field plots of 0.5 m diameter were established to simulate dairy cow urine patches. Dairy cow urine at the rate of 1000 kg N/ha was applied to the plots to simulate animal urine deposition. The nitrification inhibitor DCD was applied to some of the plots at 10 kg/ha. Some plots were un-trampled, and some were trampled with a mechanical hoof delivering the same pressure as that of an adult cow hoof walking over the field. N₂O emissions were determined using field static chamber methods.

Results

The laboratory incubation study showed that soil moisture content was a major driver affecting the growth of ammonia oxidizing bacteria (AOB) and N₂O emissions in the soil that received animal urine. Total N₂O emissions from the soil at 130% field capacity were 400 times higher than those from the soil at 60% field capacity. Total N₂O emissions were significantly related to the abundance of AOB amoA gene copy numbers but not to that of the AOA. The field plot study showed that animal treading of a wet soil resulted in a reduction in air permeability and air-filled pore space in the top 5 cm soil layer, and led to significant increases in N₂O emissions (Fig. 1). Trampling increased average cumulative N₂O emissions over a three month period from 15.9 kg N₂O-N/ha to 45.0 kg N₂O-N/ha in the urine treatments (Fig. 1). DCD was highly effective in reducing N₂O emissions, with N₂O emissions being decreased by 58-63%. Trampling did not significantly affect the effectiveness of DCD in reducing N₂O emissions. These reductions are similar to those that have been reported previously (e.g. Di et al. 2010).

Conclusions

Soil moisture status and animal treading are critical factors...
Figure 1. \( \text{N}_2\text{O} \) emissions from a field plot experiment showing the effect of animal trampling and the application of the nitrification inhibitor DCD. \( \text{LSRatio}(5\%) \) is Least Significant Ratio (5%); two treatment means differ significantly at \( P=0.05 \) if their ratio (larger/smaller) is greater than the \( \text{LSRatio}(5\%) \).

Statistical analysis:
Main DCD effect: ***
Trampling effect: ***
DCDxTrampling interaction: ns

\( \text{LSRatio}(0.05) = 1.67 \)

Di et al.
